ABSTRACT

We analyze the complete set of compact core galaxies (CCGs) in the volume-limited RESOLVE survey to investigate the formation and evolution of compact galaxies across a broad statistical distribution of environments. CCGs include both compact ellipticals (cEs) and compact cores surrounded by an envelope of gas and stars, which may represent earlier or later evolutionary stages of cEs. We select CCGs to have core-only radius < 800 pc, an upper limit that encompasses all of the similarly compact stellar systems (ultra compact dwarfs, cEs, nucleated dwarf ellipticals) included in the Archive of Intermediate Mass Stellar Systems (AIMSS) catalog. CCGs naturally occur in a range of environments from isolated to cluster. With GALEX NUV data, we derive star formation histories and find that a significant number of CCGs have recently formed stars. We compare velocity dispersions of CCGs derived from Gemini IFU data to velocity dispersions of other RESOLVE galaxies derived from SOAR spectroscopy. We search for CCGs offset to higher or lower dispersion in the dispersion-stellar mass relation, which may indicate tidal stripping or dissipative formation, respectively. Initial results show several CCGs following the dissipative formation track.

Keywords: galaxies: formation; galaxies: evolution

1. INTRODUCTION

The term compact stellar system (CSS) composes a class of galaxies that spans the radius range (~ 10 – 800 pc), lying between globular clusters (GCs) and normal elliptical galaxies (Es). Different types of CSSs include ultra compact dwarf galaxies (UCDs; [Phillipps et al. \(2001\)](#)), compact elliptical galaxies (cEs; [Faber \(1973\)](#)), dwarf elliptical galaxies (dEs), and nucleated dwarf elliptical galaxies (dE,Ns). There are many unanswered questions about these types of galaxies, typically involving how they form and evolve. One fact that makes the study of these compact galaxies so intriguing is their relative scarcity, which raises the question as to whether they are in an intermediate and short-lived evolutionary phase, or simply hard to find due to their size. Only in the last 15 years have we discovered enough (~ 40) of these objects to enable studies of their formation scenarios and evolution over cosmic time.

1.1. Introduction to UCDs

UCDs, the smallest of the CSSs mentioned above with radii ranging from 10 – 100 pc (see Figure 11 in [Norris et al. \(2014\)](#)), are largely believed to be either the high mass extension of the globular cluster population ([Drinkwater et al. \(2000\)](#), [Mieske et al. \(2002\)](#)) or tidally-stripped remnants of nucleated dwarf galaxies ([Bekki et al. \(2001\)](#), [Bekki & Freeman \(2003\)](#), [Jennings et al. \(2015\)](#), [Zhang et al. \(2015\)](#)). Meanwhile, [Norris & Kannappan \(2011\)](#) find evidence that UCDs are a “mixed bag” of both giant GCs and stripped nuclei based on their analysis of UCDs discovered near the elliptical galaxy NGC3923 and S0 galaxy NGC4546. [Seth et al. \(2014\)](#) find a supermassive black hole at the center of a UCD near M60, a massive elliptical galaxy.

1.2. Introduction to cEs

cEs, the intermediate-sized CSSs of the three previously mentioned have radii ranging typically from ~ 100 – 600 pc (again see Figure 11 in [Norris et al. \(2014\)](#)). They are typically thought to be either the result of a tidal stripping event, as is the case for the prototypical cE, M32 ([Choi, Guhathakurta & Johnson 2002](#), [Graham 2002](#)), or as a part of the low mass extension to the elliptical galaxy population. The evidence for tidal stripping includes finding tidal streams near cEs ([Smith Castelli 2008](#), [Chilingarian 2009](#)) and one cE, studied in [Kormendy 1997](#) that is believed to host a central massive black hole. (Threshed spiral scenario: [Davidge, Beck & McGregor 2008](#)). On the other hand, [Kormendy & Bender 2012](#) argue that cEs can be the extension of normal elliptical galaxies, based on

1.3. Introduction to dEs and dE,Ns

dEs and their nucleated counterparts, dE,Ns, are the largest of the CSSs mentioned with radii ranging from ~ 600 – 800 pc (again see Figure 11 in [Norris et al. \(2014\)](#)). Similarly to cEs, dEs and dE,Ns are thought to be tidally stripped remnants ([Crnojevic 2014](#) - dEs in M31 show signs of tidal stripping) or the low mass extension to elliptical galaxies ([Steve Crawford's work on high-z LCBDs](#)). They could also be the remnants of LCBDs that have been ram-pressure stripped as they entered the cluster environment and subsequently quenched. There is some evidence that dE,Ns are the progenitors of UCDs ([Pfeffer & Baumgardt \(2013\)](#), [Zhang et al. \(2015\)](#), [Liu et al. \(2015\)](#)).

1.4. Environments of UCDs

UCDs have been primarily found in clusters, such as Coma ([Price et al. \(2009\)](#), [Madrid et al. \(2010\)](#)), Fornax ([Hilker et al. \(1999\)](#), [Drinkwater et al. \(2000\)](#)), Virgo ([HaÅšegan et al. \(2005\)](#), [Jones et al. \(2006\)](#)), Centaurus ([Mieske et al. \(2009\)](#)), and Hydra I ([Wehner & Harris \(2007\)](#), [Misgeld et al. \(2008\)](#)).

Fewer UCDs have been found in groups: [Evstigneeva et al. \(2007\)](#) find one definite and two candidate UCDs in the Dorado group as well as two candidates in the NGC1400 group. Additionally, [Hau et al. \(2009\)](#) find a UCD near the Sombrero galaxy.

1.5. Environments of cEs

cEs suffer the same issue: they are mainly found in clusters ([Chilingarian et al. \(2007\)](#), [Smith Castelli et al. \(2012\)](#), [Price et al. \(2009\)](#)) and groups ([Chilingarian & Bergond 2010](#), [Huxor et al. \(2011\)](#)), but recently more have been found in an isolated environment. [Huxor et al. \(2013\)](#), [Paudel et al. \(2014\)](#). There is also recent work by [Chilingarian 2015](#) that finds more isolated

1.6. Environments of dEs

dEs have also primarily been found in groups – [Crnojevic et al. 2014](#) - dEs in M31, [Penny 2014](#)) and clusters (([Smith Castelli et al. 2012](#)), [Koo 1994](#), [Guzman 1996](#), [Michielson 2008](#), [Steve Crawford’s papers](#)).

1.7. How environments impact formation scenarios

Thus, there’s been no ubiquitous sample of CSSs that allow us to analyze the formation as a function of all environments. These studies mostly focus on selecting targets in the group/cluster environments, since this route is more convenient. Only recently have CSSs been found in the field environment ([Huxor et al. \(2013\)](#), [Chilingarian & Zolotukhin \(2015\)](#)), which highlights the need for a statistical census of CSSs that spans the group to cluster to field environments. Our goal is to create a complete and volume-limited sample of compact galaxies across all environments so that we may study their evolutionary sequences. For this, we derive our sample from the RESOLVE survey, as described in (§ 2.1). We also use the objects in the Archive of Intermediate Mass Stellar Systems (AIMSS) for comparisons to our sample (§ 2.2). We describe our sample selection process in § 2 and lastly, describe our spectroscopic data collection and analysis in § 3.

2. SAMPLES

2.1. The RESOLVE survey

We use the RESOLVE survey ([Kannappan & Wei 2008](#), [Kannappan et al., in prep](#)) as the parent sample for our census of CCGs. RESOLVE is ideal because it is an unusually complete and volume-limited survey, which allows us to find CCGs at all evolutionary stages. RESOLVE falls within the footprint of the Sloan Digital Sky Survey (SDSS, [York et al. \(2000\)](#)), and is designed to span two individual semesters: A for the spring sky and B for the fall, which overlaps much of Stripe-82. RESOLVE-A spans $\sim 38,400 \text{ Mpc}^3$ and occupies the region $131.25^\circ < \text{RA} < 236.25^\circ$, $0^\circ < \text{Dec} < 5^\circ$, and $4500 \text{ km s}^{-1} < \text{cz} < 7000 \text{ km s}^{-1}$, while RESOLVE-B spans $\sim 13,700 \text{ Mpc}^3$ and occupies the region $330^\circ < \text{RA} < 45^\circ$, $-1.25^\circ < \text{Dec} < 1.255^\circ$, and $4500 \text{ km s}^{-1} < \text{cz} < 7000 \text{ km s}^{-1}$.

RESOLVE’s exceptional completeness is due to our use of multiple redshift surveys to recover galaxies that were missed in SDSS due to fiber collisions and several issues with their photometry pipeline. These issues include the oversubtraction of sky around galaxies that causes their flux to be underestimated and thereby not meet the magnitude cut for spectroscopic follow-up; the “shredding” of galaxies in which the

pipeline breaks up a single galaxy into individual pieces, making no one piece meet the magnitude cut; and the intentional exclusion of low surface brightness galaxies ($\mu_{50} < 24.5 \text{ mag arcsec}^{-2}$), even if they meet the magnitude cut. We have used SDSS along with additional redshifts from archival sources (the Updated Zwicky Catalog ([Falco et al. 1999](#)), HyperLeda ([Paturel et al. 2003](#)), 6dF ([Jones et al. 2009](#)), 2dF ([Colless et al. 2001](#)), GAMA ([Driver et al. 2011](#)), and ALFALFA ([Haynes et al. 2011](#))) to counteract these issues and build up the survey’s membership.

With its improved redshift recovery, RESOLVE is complete down to absolute r -band magnitudes of -17.33 and -17.0 for the A and B semesters, respectively. We can convert these absolute magnitude limits into stellar mass limits: $M_\star \sim 10^{8.9} M_\odot$ for the A semester and $M_\star \sim 10^{8.7} M_\odot$ in the B semester (see Figure 7 in [Eckert \(2015\)](#)). In Figure 1, we plot the stellar masses against the deconvolved R_{eff} (see § 2.3.1) and see that these limits allow us to reach down to CSSs with sizes similar to cEs. We are not able to recover UCD-like objects, but this should not matter since we are studying CSSs as a whole in order to investigate evolutionary sequences.

An important caveat to RESOLVE’s completeness is that the survey is most likely to be missing the objects this study is focused on, cEs. This is because these objects can often be mistaken for stars in redshift surveys using tools such as the `class_star` parameter in Source Extractor ([Bertin & Arnouts 1996](#)), which uses the flux and ellipticity of an object to determine the probability of it being a star or a galaxy. There are current ongoing efforts to use photo- z estimates to recover these objects.

2.2. The AIMSS catalog

We use the Archive of Intermediate Mass Stellar Systems (AIMSS) catalog ([Norris et al. \(2014\)](#), [Forbes et al. \(2014\)](#), [Janz et al. \(2015\)](#)) as a reference sample for our CCGs. AIMSS is a catalog of spectroscopically confirmed CSSs found in groups and clusters and includes both literature and newly discovered objects. Their process to find new CSSs is as follows. First, a search is conducted in the HyperLeda redshift catalog ([Paturel et al. 2003](#)) for all galaxies at distances between ~ 7 and 200 Mpc (to ensure CSSs with $R_{\text{eff}} > 50 \text{ pc}$ will be resolved in any available HST imaging) and with $M_B < -15$. Once complete, the team then searches the Hubble Space Telescope archive for WFCP2, ACS, and WFC3 imaging within 150 kpc in projection of the selected galaxies. Next, Source Extractor is run on the HST images, and candidates are identified using a training set of previously known CSSs from the literature. Once cross-matched to ensure none are previously known and vetted by eye, spectra are obtained, redshift confirmation is performed, and velocity dispersions are extracted. AIMSS also includes literature data for (nucleated) dwarf ellipticals, dwarf spheroidals, dwarf S0s, young massive clusters, and massive elliptical galaxies. AIMSS compiles M_V , stellar mass, effective radius, and velocity dispersions for each of its objects. Thus, though not a statistically-defined sample, AIMSS provides a useful reference catalog to which we can calibrate and compare our CCGs.

2.3. CCG sample selection

2.3.1. Deconvolution of RESOLVE galaxies

In order to get accurate R_{eff} measurements for all galaxies in the RESOLVE sample, we use Galfit ([Peng et al. 2002](#)) to deconvolve the seeing point spread function (PSF) and per-

form one and two component fits on high-resolution imaging. Deconvolution is important as the smallest galaxies in RESOLVE are most effected by seeing, and accurate radii measurements are crucial for our science. High imaging resolution for the galaxies in RESOLVE is necessary to resolve compact cores down to cE-like radii. Thus, for both RESOLVE-A and RESOLVE-B, we use publicly-available UKIDSS Large Area Survey (Lawrence et al. 2007) *Y*-band data, which offers $\sim 0.8''$ seeing resolution corresponding to ~ 350 pc at RESOLVE distances.

The first step in this process is to create PSFs for each image. My process is as follows:

1. We begin by running Source Extractor on the image to identify every object and get estimates for each object’s flux, elongation, ellipticity, radius, and `class_star`.
2. With this information, we select stars to use for building our PSF. The limiting parameters are (1) that the flux must be between 5,000–100,000 counts to ensure no extremely faint or saturated stars are included, (2) that the ellipticity be ≤ 0.2 to ensure we are selecting round objects, (3) that the effective radius of the star be greater than 1 pixel to avoid selecting hot pixels, and (4) that `class_star` is greater than 0.6 to ensure the objects we’re picking are most likely stars. We also make sure the stars are not near the image edges, since there can sometimes be image artifacts there. Lastly, we make sure to not include the galaxy we are going to fit, since the cE-like galaxies can appear to be stars.
3. We next make 101×101 pixel cutouts of each object detected, with the flux peak at pixel $x = 51, y = 51$.
4. Background subtraction is then performed by taking the median of the entire cutout and then subtracting each pixel by this median value.
5. We also use the background median to reject any of the cutouts that have a background median greater than 2σ from the mean of all the background median values. This ensures we are not including any cutouts that have stars with large or bright neighboring objects. We are now left with background-subtracted cutouts of stars with no neighbors that could effect our stacking.
6. Before we can combine all the cutouts, we must normalize the flux of each central star to the same amplitude. To do this, we run each cutout through Source Extractor once more to obtain the fluxes of each central star, and use these to weight the cutouts accordingly. We calculate the weight for each cutout as follows: (1) we find the central star with the highest flux of all the cutouts and then (2) divide every flux by this maximum flux. We then divide each cutout by its corresponding weight, which makes each central star have the same amplitude.
7. We then take the median of all the weighted cutouts to create a semi-complete PSF.
8. Lastly, we normalize the semi-complete PSF from Step 7 by dividing each pixel in the frame by the total flux in the image. We find the total image flux by taking the mean of each pixel and multiplying that by the number of pixels in the image (so, 101×101). This ensures that

the final PSF image is normalized, i.e., the sum of the flux in each pixel of the cutout would equal one.

Once the PSF is complete, we fit a crude 2D Gaussian to it to determine a rough estimate seeing FWHM. The average seeing FWHM is $\sim 0.9''$, only slightly worse than the $\sim 0.8''$ seeing expected for UKIDSS imaging.

With the one and two component fits from Galfit in hand, we compare the reduced chi-square values for each fit and determine where the two component fit provides a significant improvement to the reduced chi-square of the one component fit. With each galaxy now having either a one or two component fit, we select objects that have a one component radius < 800 pc or have a two component core radius < 800 pc. The core will be the smaller of the two components fit by Galfit.

2.3.2. Selection of CCGs

We use the AIMSS sample to select a maximum radius for our CCGs: 800 pc. This upper limit ensures that we are selecting the most compact galaxies in RESOLVE, but also lets us select a range of CSSs, including cEs and dEs. RESOLVE’s lower stellar mass limit (quote, and include in RESOLVE section above) restricts us from reaching down to UCD masses.

Our sample is thus comprised of XX CCGs without envelopes (XX from RESOLVE-A, and XX from RESOLVE-B and XX CCGs with envelopes (XX from RESOLVE-A and XX from RESOLVE-B). Figure 1 shows their distribution in stellar mass and R_{eff} compared to other RESOLVE galaxies and the AIMSS CSSs.

3. DATA AND METHODS

3.1. Photometry: colors, stellar masses, and star formation rates

The RESOLVE survey overlaps with a variety of photometric surveys, including GALEX NUV, SDSS *ugriz*, and UKIDSS *YHK* and 2MASS *JHK*, and has HI data from ALFALFA and its own pointed observations with the Greenbank Telescope and Arecibo. Eckert et al. (2015) describes in detail RESOLVE’s custom reprocessing for these photometry, but the basic steps are described here.

3.2. Environmental Metrics

RESOLVE is advantageous to this study because it offers excellent environment information, allowing us to search for CCGs in all environments including groups, clusters, walls, and filaments. Moffett et al. (2015)

3.3. Kinematics

As noted in the Introduction, the velocity dispersion of a galaxy is an extremely helpful tool when testing formation scenarios. We describe the data reduction and analysis to derive σ for our CCG sample in this section.

3.3.1. SOAR spectroscopy

The RESOLVE survey gets the bulk of its spectroscopic data from the SOuthern Astrophysical Research (SOAR) Telescope, located at Cerro Tololo, Chile. We employ the Goodman Spectrograph, designed and built by UNC, along with RESOLVE’s custom-built image slicer with 3 $1''$ slits to observe galaxies in both a broad setup and either an emission- or absorption-line kinematic setup. From this absorption-line setup, we are able to derive velocity dispersions. We

use the supremely-efficient 2100 l/mm VPH grating and cover a wavelength range 4858-5503Å, which includes stellar absorption lines such as H β , the magnesium triplet, and Fe5270/5335. To achieve S/N \sim 25 per Å, we bin each central spectrum to R_{eff} .

The

3.3.2. Gemini-South spectroscopy

A subset of the smallest galaxies in RESOLVE are observed with the Gemini-South IFU for their kinematics instead of SOAR. For this absorption-line setup, we use the B1200 grating in 1-slit mode to cover a spatial region of 3" \times 5" and the spectral range 4200-5600Å. The B1200 grating offers 0.9Å resolution when binned spectrally by 2. We calculate our exposure times such that we achieve S/N \sim 25 per Å after binning by 2 in the spectral direction and summing the fibers out to R_{eff} .

The spectral reduction proceeds as follows. Using the standard IRAF Gemini-GMOS data packages, bias and overscan subtraction, spatial trimming, flat fielding and fiber identification are performed. We next use the GMOS package gemCR-spec, a wrapper for LA_COSMIC, to clean cosmic rays from each science exposure. We then correct the science frames for quantum efficiency differences between CCDs. Wavelength transformation, sky subtraction, and flux calibration are subsequently performed, and lastly, data cubes are made and summed. We then stack the individual fiber spectra out to R_{eff} to create a 1D spectrum for each galaxy that has S/N \sim 25. More information on the data reduction for the Gemini GMOS IFU can be found in the Appendix A.

3.3.3. Velocity Dispersion Extraction

We then derive the velocity dispersion (σ) from the both the SOAR and Gemini spectra using PPXF, the penalized pixel fitting code from Cappellari & Emsellem (2004). This code fits many model spectra (cite Maraston) to the observed input spectrum.

4. RESULTS

4.1. Colors and Star formation rates

* FIGURE: FSMGR vs M_{bary} /stars for RESOLVE, CCGs, and AIMSS

* FIGURE: SFR vs. M_{bary} /stars for RESOLVE, CCGs, and AIMSS

Figure #A shows the u-r colors of our CCG sample plotted against M_{bary} , compared to the RESOLVE sample as a whole. An unusual finding is that XX CCGs live on the blue sequence, a previously rare color for CSSs. REF and REF have previously found UCDs in the blue cloud but most cEs and dEs are typically thought of as being "red and dead".

Figure #B shows FSMGR vs. M_{bary} for the same objects. As with the colors, we find that many (XX%) of CCGs are forming stars at a rapid rate (XX per Gyr). This again goes against the common thought that CSSs are "red and dead".

Here discuss more the envelope vs non-enveloped CCGs and how their populations may differ.

4.2. Environments
